

MARGINAL NOTES

The Oxford House map area (NTS 53L) is in the northwestern Superior Province and is part of the Cross Lake subprovince (Stockwell, 1981) or the Sackigo subprovince (Ermannovics and Frosse, 1978). The north-central part of the area lies within the Gods Lake domain and the southern part of the Oxford House area comprises part of the Molson Lake domain.

- (1) Oxford Lake-Knee Lake-Gods Lake belt
(2) Munro Lake belt
(3) Asawiswanan Lake-Beaver Hill Lake-Goose Lake belt

Relative ages between the gabbroic belts are unknown and the stratigraphy cannot be correlated directly between the belts.

The Oxford Lake-Knee Lake-Gods Lake belt consists of a lower, mainly volcanic section (Hayes River Group - HRG) which has been intruded by tonalitic to granitic plutons and related gneisses (Bayly Lake Complex - BLC). These rocks are unconformably overlain by a volcano-sedimentary section (Oxford Lake Group - OLG) (Hubregtse, 1976 and 1985; Gilbert, 1985). U-Pb zircon data by Davis (pers. comm.) indicates an age of 2630 Ma for the upper HRG. The BLC yields ages of 2663, 2782 and 2730 Ma, consistent with field evidence that the complex gabbro possesses the HRG. An age of 2706 ± 4-2 Ma was obtained for the lower OLG and a minimum age for the OLG is indicated by an estimated age of 2692 Ma for a granite emplaced in the upper OLG.

The HRG (up to 11 km thick) comprises pillowed and massive basalt with abundant related gabbro, subordinate ultramafic sills, and minor intermediate and felsic flows, fragmentals and sedimentary rocks. The original extent of the essentially bimodal volcanic section is unknown due to intrusion or faulted contacts at the base and an erosional upper contact. At Oxford Lake, basalt in the lower HRG is mostly plagioclase-phyric whereas the upper HRG flows are mainly aphyric. Plagioclase-megacrystic basalt (locally pillowed) is a minor component of the group. The lower HRG at Oxford Lake consists largely of intravolcanic gabbros (HG) and contains sporadic ultramafic sills (HU) similar to those occurring in the middle and upper HRG at Kneelake. These rocks may include minor extrusive phases (at Oxford Lake) and possibly younger, post-HRG intrusions. Hubregtse (1976, 1978) has identified volcanic cycles in the HRG at southern Kneelake, defined by lower mafic tholeiitic sections with subordinate felsic calc-alkaline caps. Oxide iron formations occur sporadically in the HRG and a large body of volcano-derived sedimentary rocks (HV) occurs in the upper HRG at the narrows of Kneelake.

The Bayly Lake Complex (BLC) consists largely of tonalitic to granodioritic intrusions and granitic gneisses commonly layered with minor amphibolite interlayers, which may in part be derived from supracrustal rocks. The granitoid rocks are divided into:

- (1) Ophiolite tonalite-granodiorite terranes (TT) - subordinate amphibolite which occur between the supracrustal belts, and
(2) Relatively more homogeneous and massive plutons of granodiorite with subordinate tonalite (TG) which are commonly microcline-and/or quartz-phyric. The plutons occur mainly at the margins of the supracrustal belts.

U-Pb zircon data from the BLC (above) indicate plutonism lasted at least 15 million years.

The Lynx Bay assemblage in western Oxford Lake consists of intermediate volcanic fragmentals and related porphyry and sedimentary rocks. The assemblage is interpreted (Hubregtse, 1985) as genetically related to spatially associated porphyritic tonalite (BLC) and displays a lithologic zonation indicating the proximity of a volcanic centre. These rocks are characterized by intense faulting, sulphide mineralization, and hydrothermal alteration resulting in the development of chlorite and andalusite. The composition, texture and setting of the Lynx Bay assemblage are distinctly different from those of the HRG. The assemblage is largely intermediate, commonly porphyritic, with subordinate igneous country rocks, whereas the HRG is mainly mafic and aphyric, with no recognized related plutons. Contacts between the BLC and HRG are intrusive or faulted, locally with evidence of intense deformation (e.g. cataclasis near Magill Lake and blastomylonite at Gods Lake Narrows).

The Oxford Lake Group (OLG) comprises a lower, largely volcanic subgroup of related extrusive and intrusive rocks in a basin (gabbro?) up to 20 km wide extending from Oxford Lake to Magill Lake. Equivalent sedimentary rocks occur in a more restricted section in the Gods Lake Narrows. The volcanic subgroup of the OLG is significantly different from the HRG volcanics: fragmentals, not flows, are predominant; the volcanism is not cyclic and the rocks are chemically distinct, comprising calc-alkaline to tholeiitic types. The OLG rocks developed and the conglomerate conformably overlies these subaqueous volcanics. These have been reworked into the conglomerate. Elsewhere, the conglomerate is derived from the BLC and the HRG, with which it is unconformable. Vertical zonation in the OLG sediments indicates that the conglomerate is derived from the source area from the Lynx Bay assemblage down to older plutonic rocks of the BLC. Above the polymictic conglomerate (which is up to 2 m thick) are thin, shaly, fine-grained sandstones (OW) and intraformational conglomerates representing shallow-to-deep-water depositional environments, a progressive deepening of the sedimentary basin away from the underlying OLG volcanics at eastern Oxford Lake.

Two orogenic events have been recognized (pre- and post-OLG) in the Oxford Lake-Knee Lake-Gods Lake belt. Major structural trends are commonly influenced by the configurations of tectonic intrusions and thus the ages of major folds in the HRG are generally uncertain, only where folds are truncated by intrusions of the BLC (e.g. at Gods Lake) can they be determined. The HRG section is monoclinial and south-facing in the Oxford Lake-southern Kneelake area, but major folds are developed in the mafic volcanic section of the Gods Lake. Repeated tight to isoclinal folds are characteristic of the sedimentary HRG section at the narrows of Kneelake and the OLG strata. Structural uniformity between the OLG and HRG is evident at some localities, but not at outcrop scale. The unconformity is well demonstrated by truncation of early metamorphic zones in the HRG by later metamorphism, and by analysis of the metamorphic zones in the HRG (Hubregtse, 1985). The PT ratio was higher for M1 (first orogenic event, confined to the HRG) than for M2 (second orogenic event) which affected the OLG and older rocks. Major, late wrench faults with displacements estimated at up to 15 km occur within the supracrustal belts, parallel to the late faulting (Hubregtse, 1985). Major faults are interpreted along the contacts of some belts, at the contacts with tonalitic gneiss (e.g. at the south margins of the Oxford Lake-Knee Lake-Gods Lake belt, and the Munro Lake belt). Movement along these contacts was possibly initiated early and later rejuvenated, with development of blastomylonite and emplacement of concordant granitoid bodies. Several minor ultramafic intrusions occur at the faulted south margin of the Munro Lake belt.

Late intrusions associated with the second orogenic event occur at Oxford Lake (syn-tectonic Sample River granodiorite) and Magill Lake (late facies granite); the latter is a highly fractionated granite with abundant related pegmatite (Cerry, pers. comm.; Lenton, 1985). Post-OLG gabbro and diabase dykes include a pre-orogenic set (deformed by the second orogenic event) and late undeformed dykes related to the 1884 Ma Molson and late Proterozoic Mackenzie swarms (Fahrig et al., 1965; Stockwell and Mack, 1978; Machado et al., 1986).

The Munro Lake greenstone belt, interpreted as a major synclinal structure (Elbers, in prep.) is lithologically similar to the Hayes River Group. However, correlation is not established owing to lack of continuous stratigraphic differentials. Greywacke and minor argillite (commonly porphyroblastic) are more extensive at Munro Lake than in the HRG section to the north and amphibolite rather than greenschist facies is the prevalent metamorphic grade. Possible equivalents of the OLG rocks have not been found at Munro Lake. The tonalitic gneiss terrane (BLC) surrounding the Munro Lake belt may, in part, predate the latter (Elbers, op. cit.) but their relative ages and possible correlation with the HRG remain uncertain. The Munro Lake belt is more comparable with the Gods Lake belt than the supracrustal rocks of the Oxford Lake-Knee Lake-Gods Lake area (Elbers, op. cit.) but the sedimentary rocks of these belts are distinctive. Those at Munro Lake consist mainly of intermediate gabbro (commonly with cordierite) whereas at Gods Lake intravolcanic ophiolites are mainly mafic, calcic rocks (with hornblende ± cordierite) with only minor cordierite-bearing, serpentinized units. Crossbedded arkose, greywacke (G) and related granodiorite-derived conglomerate (C) comprise a section up to 2.2 km wide along the north side of the volcano-sedimentary rocks at Gods Lake. The arkose and conglomerate unit is less deformed and metamorphosed than the volcanic section to the south, and although interpreted as a tuff (Elbers, op. cit.) it is re-assigned to the upper part of the Gods Lake supracrustal section based on review of structural data and the similarity of the arkose conglomerate unit with fluvial uppermost sections of the Island Lake and Cross Lake belts (NTS 53E and 63-1).

The Molson Lake domain contains predominantly igneous rocks with migmatitic enclaves. Two distinct zones of igneous rocks are recognized:

- (1) tonalite to tonalitic gneiss with discontinuous lenses of diorite and granitic amphibolite all of which are intruded extensively by leucotonalite (TL)
(2) major granodiorite intrusions (G), a localized pyroxene monzonite body (Zx) and numerous stocks of granite to pegmatite granite.

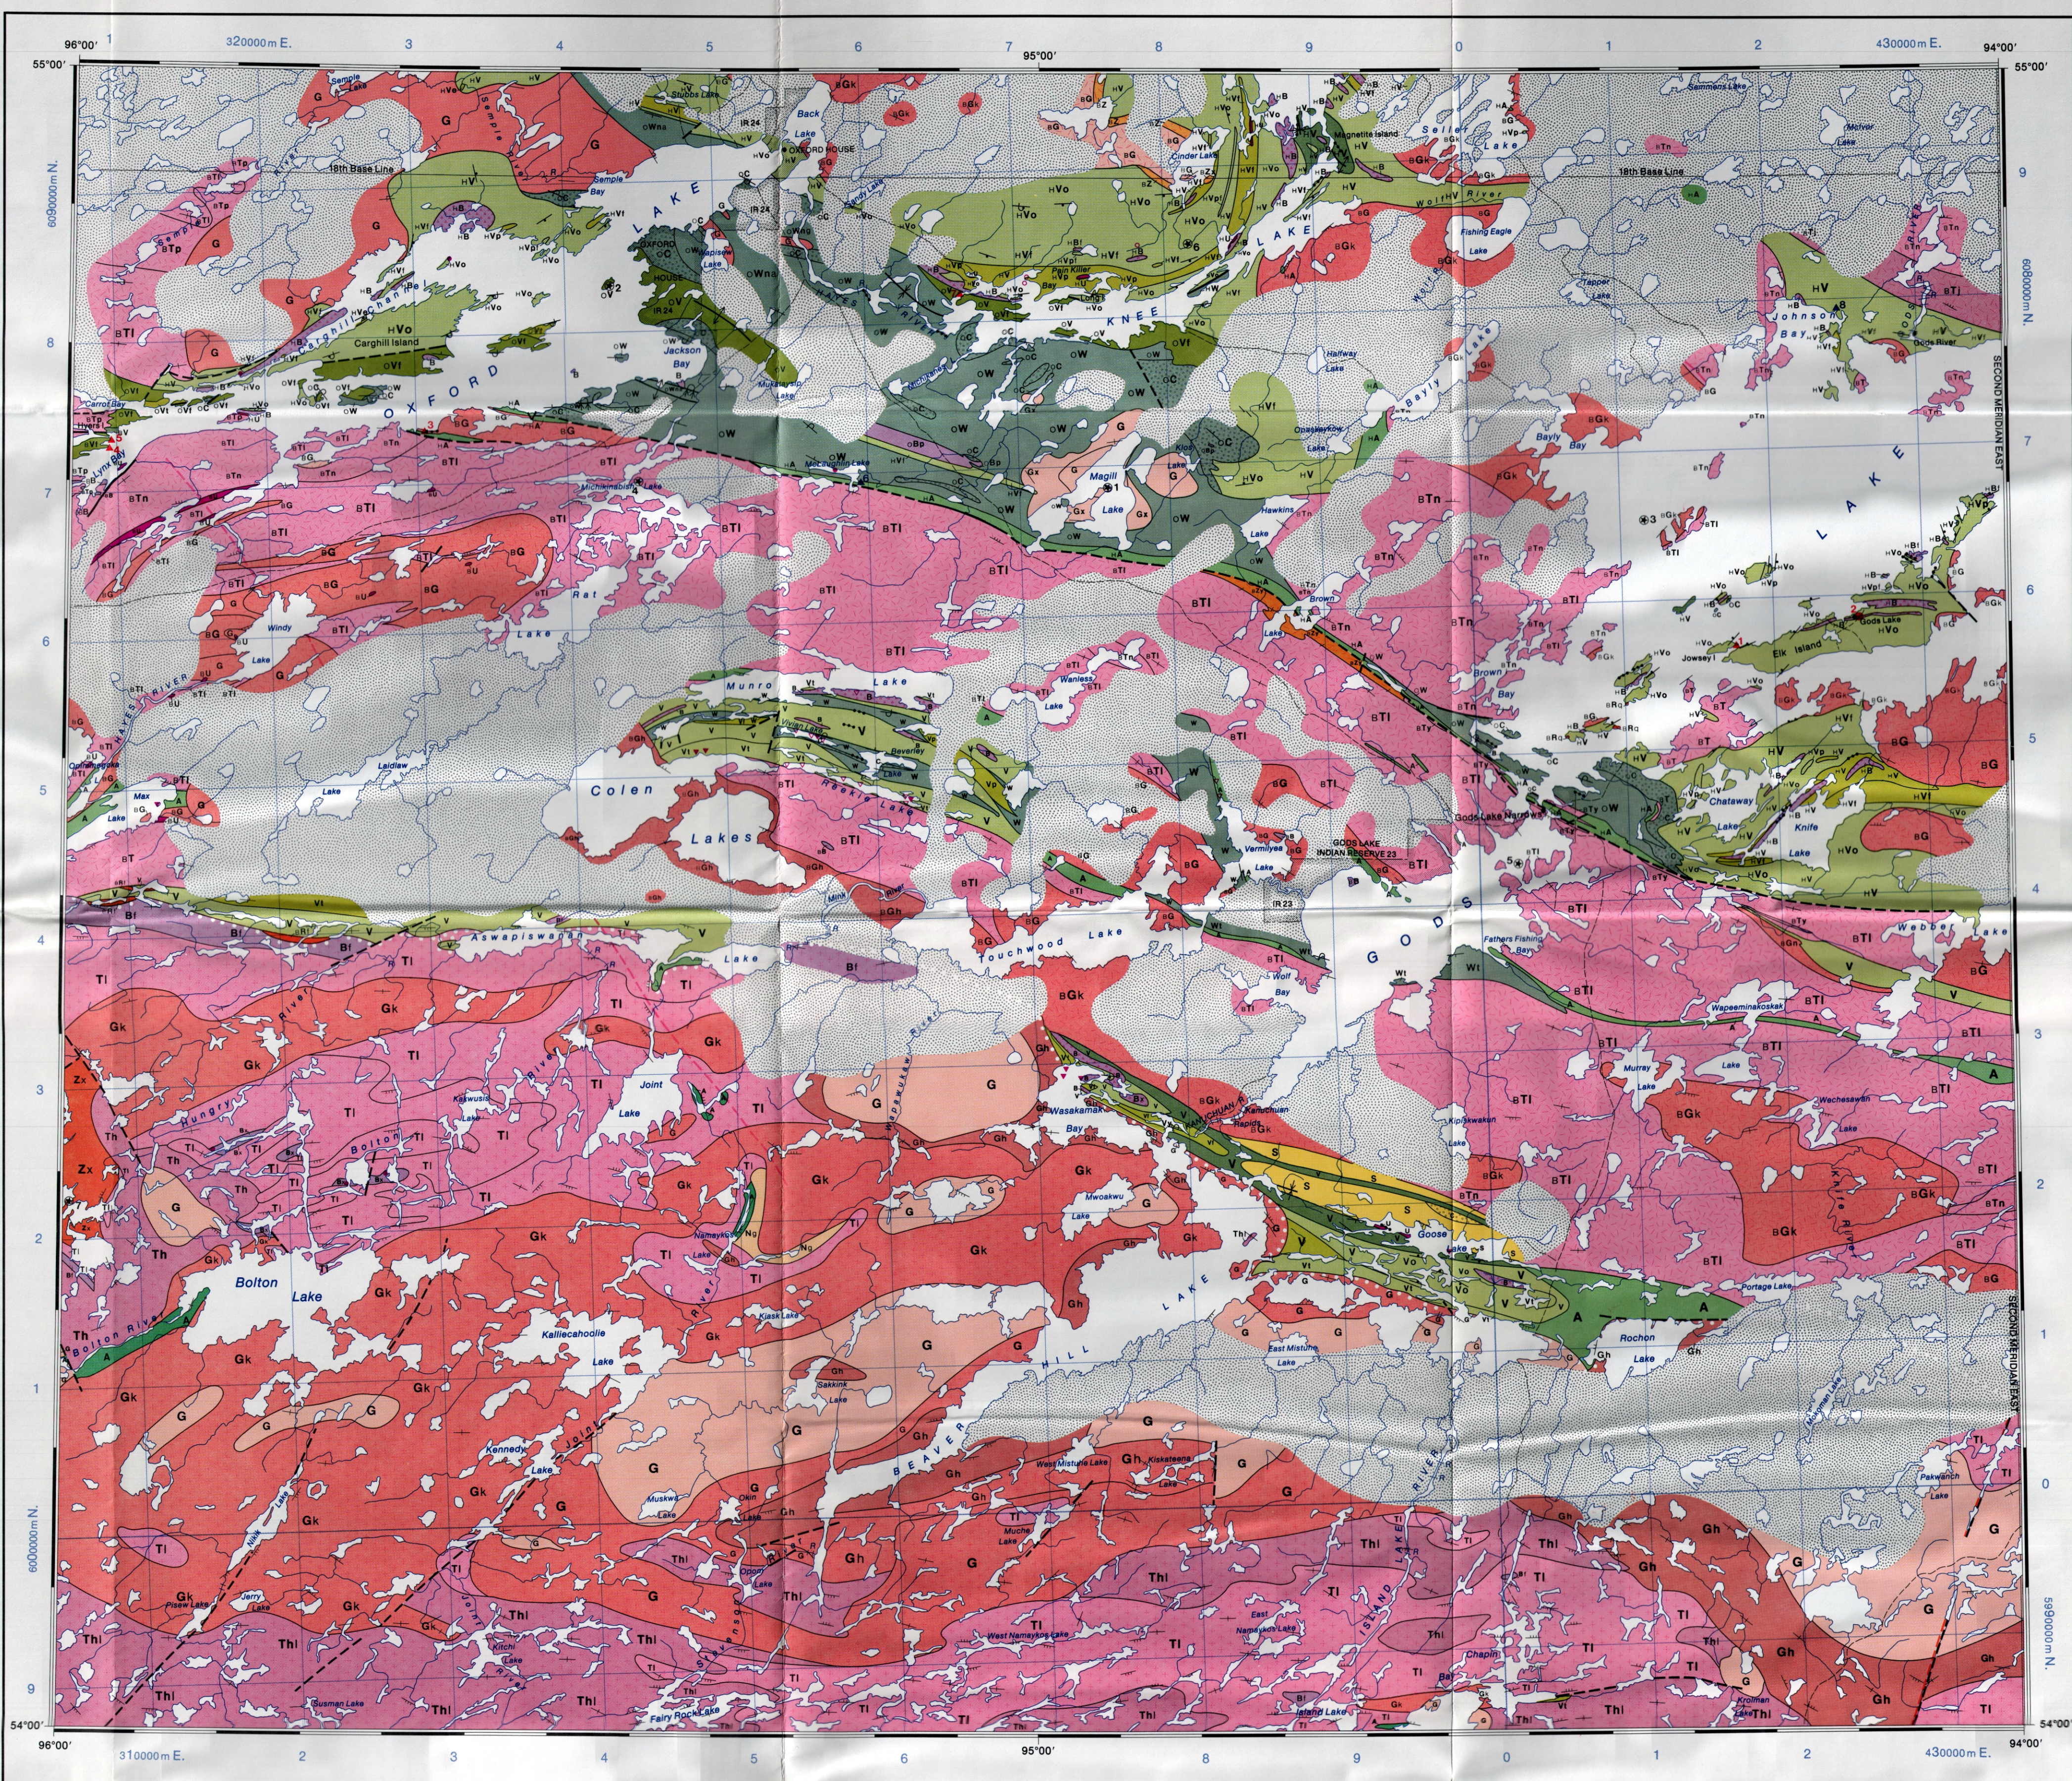

Field evidence indicates that a suite of diorites and tonalites intruded a suite of altered supracrustal rocks consisting of massive and finely layered amphibolites and variously garnetiferous, quartz-dioritic gneisses. All these rocks were pervasively intruded by leucotonalite resulting in gneiss and migmatitic enclaves of the older rocks within the leucotonalite. The suite of tonalite rocks (T) of the Molson Lake domain is similar to the granitic tonalites (aT) of the Bayly Lake Complex (Gods Lake domain).

A suite of variably deformed and recrystallized mafic (B) podolites predates the emplacement of the leucotonalite and associated migmatization but apparently predates the major granodiorite intrusions. The granodiorite rocks comprise large areas of a microcline-megacrystic phase (GA), a more localized hornblende-bearing, coarse grained phase (Gh) and a coarse grained, biotite granodiorite (G). Some areas of the leucotonalite (TL) are variably intruded by the granodiorite and are mapped as a distinct mixed or hybrid terrane (TH).

A pyroxene monzonite (Zx), which extends into the Cross Lake map area to the west (NTS 53-L), yields a U-Pb zircon age of 2705 ± 8 Ma (Turek et al., 1985). This age is identical to that of the consanguineous (T) volcanic rocks of the lower Oxford Lake Group (2706-4-2 Ma) in the Gods Lake domain. The monzonite clearly intrudes the earlier tonalitic gneiss - leucotonalite complex, but its age relative to the granodiorite suite is uncertain. Granite to pegmatite granite appears to be the youngest intrusive rock. Dykes of granitic crosscut the granodiorite and pyroxene monzonite. Granite has a uranium background value of 8 ppm but is locally enriched (Sounawala, 1979) with uranium values in the 25 ppm range (to 65 ppm).

In the Oxford House region geochemical, lithological and structural data (Hubregtse, 1976, 1985; Brooks et al., 1985; Brooks et al., 1985) have been used in a rift environment with only a few (subarctic) felsic volcanic islands on relatively thin (ca. 15 km) crust. Intrusion of the BLC - formed possibly through partial melting of a microcline-megacrystic phase (GA), a more localized hornblende-bearing, coarse grained phase (Gh) and a coarse grained, biotite granodiorite (G). Some areas of the leucotonalite (TL) are variably intruded by the granodiorite and are mapped as a distinct mixed or hybrid terrane (TH).

The absence of volcanic rocks and the occurrence of probable plutonic counterparts of the OLG in the Molson Lake domain are consistent with the interpretation of the OLG as a post-OLG unit of the Molson Lake domain relative to the Gods Lake domain. Prominent normal (?) faults such as the one on the south side of the Oxford Lake-Knee Lake-Gods Lake belt may have been caused by a tectonic regime (possibly related to uplift of the Pikwitonei granites farther north and west) which could have allowed uplift of the south margin of the Munro Lake belt with ultramafic lenses may represent reverse faults or thrusts.

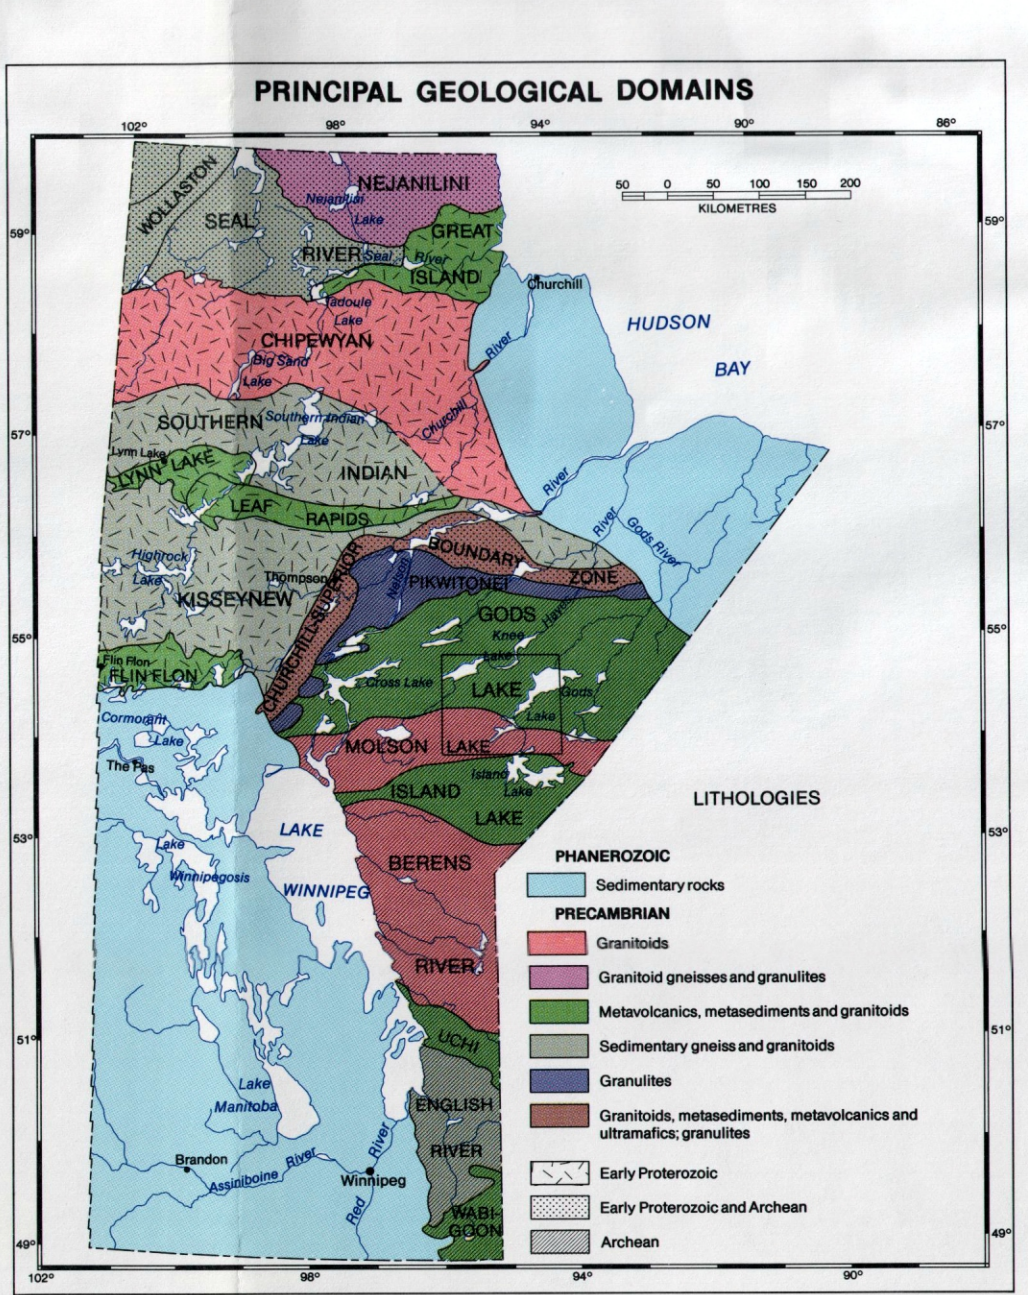

Scale 1:250,000. Printed 1988.
